¹AMAVILAH is an adjunct instructor of economics at Glendale College in Arizona (USA), and a principal of REEPS, which consults and publishes occasional papers on resources, technology, and the engineering economy of economic growth of small open economies. The ideas expressed here are his own alone. He can be reached at either vhs@ziplip.com, amavilah@msn.com, or the address above.

Human Capital and Income Generation across U.S. Native American Reservations and Trust Lands

Abstract: The current research emphasis on institutions as key determinants of economic performance has uncovered important questions for further research. For example, if institutions are central to economic performance, then what explains observed differences in performance across parts of one economy sharing similar institutions? This paper suggests that two broad aspects of institutions are involved - infrastructure and superstructure. It develops and then applies a simple model to 50 U.S. reservation economies to assess how the two aspects affect income. The results show that resources and resource productivity are necessary but insufficient determinants of income in reservation economies. Human capital is a constraint for two institutional reasons. First, infrastructures for fostering human capital are either inadequate or inappropriate. Second, the local superstructure seems resistant to existing infrastructures that were supposed to enhance human capital formation. Since infrastructural and superstructural aspects of institutions are competitive rather than complementary, the Nelson-Phelps channel for transmitting external technology into USRATLs appears clogged up.

Keywords: Income constraints, infrastructure, superstructure, institutions, human capital, Native American reservation economies

ECONOMIC GROWTH THEORIES have long argued that differences in economic performance across economies are due to a combination of differences in factor endowment, factor productivity, and technology. An obvious reading of these arguments is that parts of one economy should perform the same, *ceteris paribus*, due to interactions among the parts via trade, human capital, and even geographical location (Moreno and Trehan, 1997). Yet **U.S. Native American Reservations and Trust Lands (USRATLs)** differ in economic performance among themselves as well as from their host(s) - the general U.S. economy and U.S. state economies - of which they are parts, often with enormous implications for Native Americans (USDOC/EDA, 1996, Cornell and Kalt, 1998).² For example, during the 1990s the average unemployment rate among Native Americans was above 20%, in some cases topping 35%, compared to a four to six percent rate of natural unemployment for the USA as a whole (Cornell and Kalt, 1998). Taylor and Kalt's (2005) analysis of 2000 census data report remarkable economic growth for the 1990-2000 decade. However, from the 1990 perspective the U.S. national median family income of \$35,000 is still higher than that for Native Americans at about \$21,000. A large gap exists between the Native American per capita income of only \$8,284 and the U.S. national average of \$14,420 (Vinje, 1996; Mushinski and Pickering, 2000; Pickering and Mushinski, 2001). Furthermore, only 43.3% of Native Americans 18 years and older compared to 53.1% or more for all Americans have a high school degree.

²USRATLs are defined as "areas with boundaries established by treaty, stature, and/or executive or court order, and recognized by the Federal Government as [a] territory in which American Indian tribes have jurisdiction. State reservations are lands held in trust by State governments for the use and benefit of a given tribe. Trust lands are property associated with a particular American Indian reservation or tribe, held in trust by the federal Government. Trust lands may be held in trust either for a tribe (tribal trust land) or for an individual member of a tribe (individual trust land)." For brief definitions of all three designation see <http://factfinder.census.gov/metadoc/1990stf3td.pdf> or the US Bureau of Census and Bureau of Indian Affairs (BIA) for details.

What is the explanation for the difference in economic performance between USRATLs, and the U.S. economy? Some researchers like Cornell and Kalt (1998) stress the importance of sovereignty and nation-building as determinants of long-run economic prosperity. Chase-Dunn and Hall (1998) on the other hand use a periphery-center model to demonstrate how in the past economic activities such as trade have depended on tribal networks and conclude that the recent decline in the economic performance of USRATLs is a consequence of weakened tribal social capital. Even so, there is a discernible consensus that economic growth across USRATLs is not only about the lack of resources and simple expertise alone (Henson, 2003).

The objective of this paper is to assess economic performance of USRATLs (measured as aggregate and average income), using a novel model that is capable of distinguishing infrastructural from superstructural effects of institutions on performance (Amavilah, 2004a). The next section below provides a brief summary of the relevant literature. Section 2 specifies the equations to be estimated. The third section extends the models developed in Section 2 to allow for separate estimates of infrastructural and superstructural effects of institutions on economic performance. Section 4 describes the key measurement issues (variables and data), while Section 5 presents the estimation results. Concluding implications for policy and further research fall under the last section.

1. Brief Summary of Literature

Many generations of economic growth theorists have sought to explain how (and why) economic performance differs across economies, e.g., Denison (1967); Solow (1956; 1957), Arrow (1962); Easterly (2002); Temple (1999); and Lewis (1954). The Denisonian efforts focus on

changes in the quantity and quality of resources, while Lewis influences studies that see the problem of differential performance in terms of the dualistic structure of some economies in which a “modern” (urban) sector and “backward” (rural) sector coexist. According to Lewis the solution to differential performance comes from the employment by the modern sector of a surplus labor in the backward sector. However, the optimal solution for Lewis’s model is too dependent upon continuous and fast expansion of the modern sector. A likely glitch is that the flow of labor may raise average wages in rural areas, but potentially lower urban average wages as well. Just as it is simplistic to pin growth on resources alone, so too it would seem dual economy models are hardly useful tools for describing USRATLs and their relationships to the host economy. After all USRATLs are dual themselves.

Other strands of growth research and practice stress the political economy of economic performance in which comparative growth rate differences are due to the interactions of political and economic factors (Mueller, 1983). The ideas generated by this emphasis marked the beginning of influential works like those by Romer (1986,1989), Mankiw, Romer, and Weil (1992), Barro (1991, 1994), and Barro and Sala-I- Martin (1995) which concentrated on adjusting labor for quality (Romer, 1990; 1994; Solow, 1994; Pack, 1994). The productivity gains from that concentrated specialization ushered in the new growth models, according to which economic growth is a function of both “objects” and “ideas”, using Paul Romer’s manner of speech. A key distinction between ideas and objects is that while objects are subject to the initial conditions of the economy and subsequent diminishing returns to scale, ideas are not. In idea-driven economies scarcity is a blessing that gives incentives to innovations. Hence, different economies should still grow at different rates even if their objects and object productivities are the same. Thus, despite their shortcomings as Pack (1994) points out, the new growth models renew an old idea that resources can, perhaps must, be treated as

endogenous determinants of economic growth (Lucas, 1988, 1993, Grossman and Helpman, 1991, Romer, 1990, 1993, 1994).

The common problem with all these models is that the sources of factor productivity differences remained almost unexplained until the recent revival of Adam Smith's thesis that institutions are central to economic performance. Smith's reincarnations such as Sir W. Arthur Lewis (1965) argue that overlying resources are historical, philosophical, and social structures that motivate and sustain "*the will to economize*" (Lewis, Chapter 2). It is little wonder that Hall and Jones (1998, 1999) attribute differences in average labor productivity across countries to institutions, broadly speaking, or social infrastructure particularly (cf. Polanyi, 1957; Hodgson, 1988; North, 1990; Acemoglu, Johnson, and Robinson, 2001; Lee, 2002). While treading cautiously in Rodrik (2004), Dani Rodrik, Arvind Subramanian, and Francesco Trebbi (2004), declared that "institutions rule" economic development. Sacks (2003), and Glaeser, La Porta, Lopez-d-Silanes and Shleifer (2004) question the primacy of institutions in favor of geography and human capital respectively. However, the debate and evidence in both cases remain consistent with the model in which Smith defended the creation of institutions for progress (Angresano, 1992). Institutions are crucial to economic performance because they define the social relationships surrounding economic activities, and enable economic agents to pursue their self-interests (Smith, 1957, 1974). Yet, and although it is sufficiently clear that the differences in factor productivity across countries come from differences in institutions, extant literature on this topic does not make it nearly as clear as to whether it is the infrastructure or the superstructure that is crucial to economic progress. Do, and should, economies with similar institutions perform the same? What are the implications of the answer sustainable for the USRATLs? - That is the problem.

2. Economic Performance across USRATLs

2.1 Aggregate Economic Performance

Let aggregate income (Y_i) be a measure of the economic performance of the i th USRATL. Next, let Y_i be produced from local technology (A_i), *economically capable population* (N_i), and physical capital (K_i). Because USRATLs are embedded economies, Y_i is also influenced by the economic condition (Y_j) and the state of technology (A_j) of the host economy, i.e., $Y_i = f(K_i, A_i, N_i, Y_j, A_j)$. Assume that A_i augments L_i , Y_j affects Y_i directly, and A_j affects Y_i indirectly through N_i . By treating N_i as decomposable into raw labor (L_i) and human capital (H_i), and supposing a multiplicative production function,

$$\ln Y_i = A_0 + \alpha \ln L_i + \beta \ln K_i + \gamma \ln H_i + \delta \ln Y_j + \mu_i. \quad [A_0 = \ln A_i + \ln A_j]. \quad (1)$$

Human capital (H_i) in (1) is the equivalent of the quality-enhanced component of either total labor (L_i) or the economically capable population (N_i), and is given by

$$\begin{aligned} H_i &= e^{\phi_i S_i} L_i & (a) \\ H_i &= e^{\phi_i S_i} N_i & (b), \end{aligned} \quad (2)$$

where S_i is a neoclassical measure of H_i such as years of schooling.

Eq. 2(a) is deficient in that it is based on L_i , making H_i too narrow base by failing to recognize that the rate of diffusion of technology is a function of the capacity rate of the embedded economy (Rogers, 1983, p. 233). Thus, (1) is mistaken (i) in arguing that the values of both human capital and

raw labor become zero come retirement age or unemployment, and (ii) in its implication that children do not own human capital before the legal working age. In practice human-capitalized people continue to add value to economic performance even when they are not directly employed in production, which contrasts to conventional approaches such as those by Sianesi and Van Reenan (2003), and Harnom, Oosterbeek, and Waltker (2003), which measure returns to H_i only as returns to education.³ Hence, (2b) is preferable to (2a), and so it is easy to interpret $A_j N_i$ as the Nelson-Phelps (1966) channel that allows the flow of A_j via H_i from the host(s) to embedded economies.

2.2. Average Economic Performance

Dividing by L_i and taking the natural logarithms of both sides of (1) gives the (log) labor productivity as

$$\ln y_i = \alpha_0 + \beta \ln k_i + \gamma \ln h_i + \delta \ln y_j + \mu_i, \quad (\alpha_0 = \alpha \ln A_i + \gamma \ln A_j), \quad (3)$$

where $k_i = K_i/L_i$, $h_i = H_i/L_i$, and $y_j = Y_j/L_j$ can be read either as a spill-over effect of the host economy on the local economy, or as a relative measure of what U.S. labor productivity would be if U.S. output were produced by local labor alone.

3. Economic Performance and Institutions

3.1 Mining Population for Human Capital

³This is an old idea on how cultural factors can aid or inhibit technical change, available, in one form or another in Bury (1932), Mead (1953), Cipolla (1965), Volti (1992), Rogers (1983), Pytlik, Lauda, and Johnson (1985), Adelman and Morris (1967), Temple and Johnson (1998), Coleman (1990), Fryer (2003), and Nisbet (1980). The term “institutional sclerosis” has also been used to make this very same point, see, e.g., Choi (1983: Chapters 3 and 9).

It is common practice to estimate (1) and (3), assuming $H_i = e^{\phi S_i} L_i$. However, H_i is an institutional variable; its biological basis has an institutional setting. Decisions about procreation, raising children, health, education, etc. are all informed by institutional constraints and prospects. Hence, $H_i = e^{\phi S_i} N_i$ is the appropriate measure of human capital. The question is: How does one measure N_i ? To answer that question I introduce the Lasky quantity-quality model familiar to economic geology, mining and geological engineering, and mineral economics. In its original use the Lasky model illustrates the responsiveness of a stock (quantity) of resource, such as a mineral ore, to its average grade (quality) in one deposit or across deposits (Lasky, 1950).⁴ By analogy N_i is a rich stock that can be “mined” for human capital. The Lasky adaptation represents an inverse relationship between the log of (cumulative) stock of economically capable people (N_i) and its corresponding average quality (\bar{q}_i), i.e.,

$$\ln N_i = \theta_0 + \theta_1 \bar{q}_i \Rightarrow \bar{q}_i = \lambda_0 + \lambda_1 \ln N_i, \quad [\lambda_0 = \theta_0 / \theta_1 > 0, \lambda_1 = 1 / \theta_1 < 0], \quad (4.1)$$

for which

$$N_i = e^{\theta_0 + \theta_1 \bar{q}_i}, \quad H_i = e^{\phi_i S_i} [N_i] = e^{\theta_0 + \theta_1 \bar{q}_i + \phi_i S_i}. \quad (4.2)$$

If

$$L_i = \psi N_i, \quad H_i = e^{\phi_i S_i} [\psi N_i] = \psi [e^{\theta_0 + \theta_1 \bar{q}_i}] = \Psi [e^{\theta_0 + \theta_1 \bar{q}_i + \phi_i S_i}]. \quad (4.3)$$

⁴ Following Harris (1993), Amavilah (2004a) outlined two other models of this type.

Eq. (4) says that measured conventionally, S_i is neither an accurate nor an adequate measure of H_i . Here is further evidence. According to the standard models, the desirable (target) level of human capital (H_i^*) is

$$H_i^* = (1 - \sigma)e^{\phi S_i} L_i = e^{\phi S_i} L_i, \quad \sigma = 0, \quad 0 < d \ln H_i^* / d S_i = \phi < 1. \quad (5.1)$$

Eq. (5.1) suggests that there is no human capital drain, either because L_i is fully employed already, or because, being tied to local A_i , it is unemployable outside the embedded economy. However, with nonzero human capital drain,

$$H_i^* = (1 - \sigma)e^{\phi S_i} N_i = (1 - \sigma)e^{\theta_0 + \theta_1 \bar{q}_i + \phi S_i}, \quad 0 < \sigma < 1 \Rightarrow d \ln H_i^* / d \bar{q}_i = \theta_1, \quad d \ln H_i^* / d S_i = \phi \quad (5.2)$$

Eq. (5.2) means that A_j transforms N_i into H_i^* that can be employed *inside* and *outside* of USRATLs, and σ would be nonzero as well. Hence, $H_i^* < H_i$, but H_i^* depreciates slower than it appreciates.

3.2 Infrastructural Versus Superstructural Aspects of Institutions

The influences of H_i on Y_i reveal the strengths or weaknesses of institutions as determinants of economic performance. The question is: What part(s) of institutions? To answer this question one can take advantage of a Marxian dichotomy which states that institutional determinants of economic growth can be infrastructural and superstructural. The dichotomy refers to the dynamics underlying production forces and social relations in transforming the material conditions of the economy - the basic infrastructure. However, infrastructural changes alone do not make progress, because infrastructure without superstructure is like a skeleton without flesh (Marx, 1906, 1973; Cornforth, 1962; cf

Rosenberg, 1982, pp. 34-51). The Lasky model permits one to separate the two dimensions of institutions by letting S_i proxy infrastructural elements of institutions, while \bar{q}_i represents the superstructural components of institutions. Then the appropriate human capital, with the possibility of H_i^* drain, becomes

$$H_i^* = (1 - \sigma)e^{\omega X}(N_i^*), \quad (6)$$

where ω is a vector of parameters θ and ϕ , X is a vector of variables S_i and \bar{q}_i , and $N_i^* = N_i - L_i$ is the desired level of N_i . For $0 < \sigma < 1$, $H_i^* < H_i$. The implication of (6) is that it combines infrastructural and superstructural factors in its first term, infrastructural elements in its second term, and the difference between the two terms stands for purely superstructural factors.

4. Measurement Issues: Variables and Data

The data for this study comes mostly from *The Statistical Record of Native North Americans (1996)*. The *Statistical Record* draws its data from the 1990 U.S. Bureau of Census and the Bureau of Indian Affairs' documents. Other sources of data used here are indicated as the need arises. The data collection focuses on a sample of 50 of the largest Reservations and Trust Lands (USRATLs) listed in Table 0.0, and covers the variables described below.

Local Dependent Variables (Y_i, y_i)

The dependent variables are aggregate (Y_i) and average (y_i) income in millions (thousands) of 1990 U.S. dollars. I assume that (Y_i, y_i) is approximately equal to the value of local production, and treat income and output interchangeably.

Local Independent Variables

Investment (I_i) and Capital (K_i, k_i):- Most empirical studies calculate current capital stock (K_i) mainly by the “perpetual inventory method”. Unfortunately, no data on either capital or investment was readily available. Instead, I found aggregate data on sales and receipts of all Native American-owned firms (ASR) by state and corresponding data on sales and receipts of Native American-owned firms with paid employees (WSR). One can argue that if capital is not paid it due, then the difference between ASR and WSR is *apparent profit* that was re-invested. The relationship between investment and expected profit is a clear one: high profit expectation drive demand for capital, making profit a reasonable proxy for capital. Hence, it is assumed that $K_i \approx \text{ASR} - \text{WSR}$.⁵

Population: - The population of any economy is a significant resource as well as a constraint. As a resource economies with high population have high aggregate income; as a constraint a high population means low average income, and even lower per capita income. Examination of the Native American population by age shows that the bulk of the population is in the 22 -59 and older group. Also from this examination there is a strong indication that Native Americans accumulate human capital later in life, the accumulation process often continues past retirement. This regularity runs against my *a priori* expectation that with technological advancement there would be a backward and forward propagation of human capital formation.

Total Labor (L^*) and Workforce (L_i):- The labor force (L^*) is workforce (L_i) plus the number of unemployed workers. The conventional and extended measures of human capital (E_{ii}, S_{ii}) are based on L_i as I show below.

⁵ The problem here is that when this proxy is applied equally it favors smaller USRATLs located in large states like California. We offer no remedy for this bias at this time.

Economically Capable Population (N_i):- This variable includes all *economically capable* people aged 14 - 74 years. Some people who are 16 - 65 years of age already belong to L_i , so that N_i is the sum of L_i , pre- L_i aged 14-15 years, and post- L_i aged 66-74 years. A detailed investigation of the data shows that the majority of L_i is in the 22-59 year age group, and it is here where unemployment has the worst effect, because at that age many people are married or are considering marriage and family. But since graduation from both high school and college comes later in life, it appears that full-time careers start late in life, and often lasts past the typical retirement age of 65. Also past the retirement age, private sector employment of persons 66-74 years old falls, while self-employment, and employment in traditional occupations increases, which tends to reduce the transmission of A_j . Variables E_{2i} and S_{2i} outlined below are based on N_i .

Human Capital (H_i, h_i):- Note that variable S_i has three dimensions to it. The first dimension is educational attainment measured here in two ways. In the first E_{1i} is the ratio of workers with high school or better education to the total workforce (L_i). The second measure of S_i is the number of people with high school or better education relative to the economically capable population (N_i), which I designate by E_{2i} . From previous literature the E_{ki} dimension accounts for two-thirds of the S_i index.

The second dimension of S_i is “Health”. The rationale for this dimension is that a healthy population is likely to be physically and mentally more productive than a “sick” population. High productivity enables a population to earn high income. *Ceteris paribus*, with high incomes, a healthy population can stimulate and sustain human capital accumulation, reduce human capital depreciation, and probably increase the rate of human capital drain (Bloom, Canning, and Sevilla, 2004). Here we measure “Health” by the average life expectancy (Life) of Native Americans over the 1980-1990 decade, calculated as

$$Life = \frac{LifeAct - LifeMin}{LifeMax - LifeMin} = \frac{71.5 - 61}{74.9 - 61} = 0.755, \quad (7.1)$$

where *LifeAct* is actual life expectancy, *LifeMin* is the minimum life expectancy, which is what life expectancy was in the 1960s-1970s, and *LifeMax* is average life expectancy of all US racial groups.

The third and last dimension of S_i , “Other”, summarizes in percentage terms Native American representations in radio and television (0.002), law and law enforcement (0.005), electoral process (0.2002), and Native American objective attitudes toward governance (0.4763), i.e., $Other = 0.002 + 0.005 + 0.2002 + 0.4763 = 0.7215$.

The “Health” and “Other” variables account for 1/6th of S_i such that

$$\begin{aligned} S_{1i} &= 1.47265 + 0.667 * E_{1i} \\ S_{2i} &= 1.47265 + 0.667 * E_{2i}. \end{aligned} \quad (7.2)$$

In general $S_{ki} = a_0 + bE_{ki}$, which implies that all USRATLs are equally disposed to human capital accumulation, given the initial condition, $a_0 = 1.47265$.

The three dimensions of S_i reflect institutional processes and systems that require investment in physical capital (schools, hospitals, public systems, etc.). Hence, they represent infrastructural aspects of institutions. To measure superstructural aspects of institutions I construct \bar{q}_i as an index of local cultures and traditions that assist or resist H_i building, and through it the transmission of A_j via H_i . I argue that cultures and traditions can be open or closed to external influences, and construct \bar{q}_i in a multidimensional way so that it is capable of capturing superstructural effects of institutions. First, I

consider the ratio of people who served or are currently serving in the U.S. military to N_i (r_{m2n}). The military exposes servicemen and women to other cultural and traditional experiences. Hence, a high military- N_i ratio implies greater cultural openness. Second, I look at the ratio of languages spoken at home to the English language (r_{h2e}). In a closed economy people are more likely to speak their home languages than foreign languages, including English, if that is foreign to them, and the ratio should be high. Third, I take the ratio of Native Americans residing on tribal areas to those enrolled in respective tribes (r_{r2e}). If $r_{r2e} = 1$, the tribal economy is completely closed; if $0 < r_{r2e} < 1$, the economy is *open inwards*, hence more people live on tribal land than are enrolled in that tribe. And if $r_{r2e} > 1$, the economy is *open outward*, i.e., more people are enrolled in the tribe than reside on tribal lands. An inwardly open economy is potentially more accepting of the inward flow of A_j than an outwardly open economy. Fourth, we consider the ratio of people in tribal occupations to N_i (r_{t2n}). The higher this ratio, the more closed the economy. Finally, I take the ratio of people with telephones to those without (r_{t2nt}), the rationale being that one would have telephone services only if some external communications need to be maintained. For $r_{t2nt} > 1$, the economy is open and accepting of external technologies. Thus,

$$\bar{q}_i = \sum_{i=1}^{M=5} r_i, \quad 0 < r_i < 100\%. \quad (8)$$

A priori expectations are for the effects of S_i and \bar{q}_i on performance to be positive and negative, respectively.

External Variables: Conditions of State and National Economies (Y_j, y_j) and Technology

(A_j):- The condition of U.S. states (Y_s, y_s), and those of the entire U.S. economy (Y_u, y_u) affect the

performance of USRATLs (Y_i, y_i), where $(Y_u, y_u) = \text{real U.S. GDP MINUS } (Y_i, y_i)$, and real state products (Y_s, y_s) LESS (Y_i, y_i) .^a Many Native Americans have full-time equivalent (FTE) employment with the federal, and local and state governments. In addition different federal departments support many programs for Native Americans. Support for these programs ebbs with the condition of the national economy. Data for these variables came from the *Statistical Abstract of the United States: 2003*, 123rd Edition. A_j is assumed to be exogenous and to flow to USRATLs via H_i .

5. Estimation Results

Given full information on human capital drain and depreciation, the appropriate human capital to use is (5) and/or (6). Without such information I utilize (4) so that the equation for estimating aggregate income (output) is

$$\ln Y_i = \alpha_0 + (\alpha + \gamma) \ln L_i + \beta \ln K_i + \phi S_i + \theta \bar{q}_i + \delta \ln Y_j + \mu_i, \quad [\alpha_0 = \alpha \ln A_i + \gamma \ln A_j + \theta_0]. \quad (9.1)$$

The average of (9.1) is

$$\ln y_i = \alpha_0 + \beta \ln k_i + \phi S_i + \theta \bar{q}_i + \delta \ln y_j + \mu_i, \quad [\alpha_0 = \alpha \ln A_i + \gamma \ln A_j + \theta_0], \quad (9.2)$$

where, again variables S_i and \bar{q}_i measure institutional effects of human capital performance.

U.S. Native American Aggregate Income

Table 1.1 reports estimation results given the economic conditions of the U.S. states in which USRATLs are located. From these results the impact of capital on aggregate income ranges from -0.02 to

^aCapital letters represent aggregate variables, and lowercase stands for average.

+0.19. The negative effect of capital on aggregate income is not statistically different from zero, and it is similar to what Amavilah (2004b) finds with respect to 84 U.S. Native American economies, and it is also comparable to the steady state impact of 15.5% reported by Holtz-Eakin (1993) for U.S. states.

From the same table the effect of an additional worker on aggregate income is an extra \$68.00 per year. However the potential gain in aggregate income due to one more raw labor is all but wiped out by the decline in aggregate income resulting from an increase in human capital, defined as E_{1i} and S_{1i} . The situation is no better with respect to E_{2i} and S_{2i} for which partial coefficients are as low as -9.30. These results are consistent with Vinje's (1996) -7.8 partial coefficient of educational attainment with respect to income of 23 Western reservations. The implication of the negative effect of education on income suggests that human capital accumulation weakens, or is perceived to weaken, tribal commitments such as tribal membership and allegiance and is thus not well-received. On the other hand, high educational attainment increases human capital drain. Both rationalizations are consistent with the negative impact of \bar{q}_i on aggregate income. Fortunately, the increase in the economic condition of host states tends to increase aggregate income by \$26 per year. Up to 58% of variations in aggregate income are explained by the included variables, but the R-square statistic may be misleading given large constant terms.

From Table 1.2 the impact of the USA economy as a whole on aggregate income of USRATLs is more than double that of the host states; the partial coefficient of regression ranges from 0.41 to 0.59 with up to 56% of variations in aggregate income explained by the included variables. Deviations about the mean fall below one standard error of the estimate, which suggests good predictive power. Even so, large constant terms were suppressed, and that should caution interpretation of the results. However, parameter estimates are consistent; changing labor by one unit, holding other factors constant, increases aggregate

Figure 1- Actual and Estimated Aggregate Income of Selected SRATLs, 1990

Figure 2- Actual and Estimated Average Income of USRATLs, 1990

income by \$69 per year. Holding labor unchanged and raising capital investment by one dollar, results in a 19% rise in aggregate income per year. Similar results are generally found for developing countries.

By all measures used in this analysis, human capital tends to reduce aggregate income; the coefficients range from a low of -9.6 to a high of -0.96. This means that infrastructural components of institutions responsible for human capital formation in USRATLs are weak, while at the same time USRATLs appear to resist human capital formation most likely because of its association with external technology. The latter suggests the importance of culture in economic performance as described by Mushinski and Pickering (2000), and Pickering and Mushinski (2001). One way of reversing the negative effects of human capital on the aggregate income of USRATLs is to either strengthen infrastructural elements, or neutralize superstructural resistance to institutions expected to foster human capital formation.

U.S. Native American Average Income

Tables 2.1 and 2.2 show that average income of USRATLs depends on physical capital accumulation: holding labor constant, one dollar's worth of investment in physical capital, adds an extra \$0.50 to average income, which is in the same ballpark as the 0.61 coefficient of K/L ratio often found for developing economies. The fact that it is above the "1/3 rule", suggests capital scarcity. As in the case with aggregate income, infrastructural aspects of institutions measured as E_{ki} or S_{ki} , are weak, and in the presence of superstructural pressures represented by \bar{q}_i , human capital tends to reduce the average income of USRATLs. The economic conditions of host states contribute significantly to the average income of USRATLs. If the gross state product rises by one dollar, the average income of a representative USRATL increases by anywhere from eleven to forty-eight cents.

Given the included variables, 28% of variations are well-explained. In fact, if we consider the impact of the entire U.S. economy on the average income of USRATLs, the coefficient of y_u rises to 0.78

from 0.48 with respect to the host states. In this case, the K/L ratio contributes 19.4% toward the average income of USRATLs. But here too the results show that infrastructural limitations combine with superstructural resistance of institutions to affect average income negatively, with up to 75% of variations explained by the included variables.

6. Concluding Remarks

Figures 1 and 2 summarize the results with a selection of estimations from Tables 1 and 2. Figure 1 compares actual to estimated aggregate income. Aggregate income for USRATLs falls between \$8.9 million and \$485.2 million, with the majority of USRATLs falling in a narrow income band ranging from \$24.2 million to \$178.5 million. In terms of average income the corresponding band ranges from \$22.0 thousand to \$442.4 thousand, but across the board average income falls between \$2.98 thousand and \$1.2 million. Both aggregate income and average income are rising, but at decreasing rates.

The results show that the aggregate and average incomes of USRATLs both depends on resources and resource productivity. On balance the coefficient of K and K/L ratio is a robust 19%. The partial impact of physical labor on income is generally higher than that of physical capital. USRATLs perform like developing countries, and like other developing economies the effects of resources and resource productivity on income are not strong enough to foster meaningful H_i accumulation. Hence, the main constraint on economic performance in USRATLs is human capital, whose effect on income is generally negative.

Previous research explains the negative coefficient of human capital in three ways. Some argue that developing economies have a low initial stock of human capital to begin with. Others suspect some kind of identification problem inasmuch as level and growth effect of human capital on growth are hard to separate. Still others like Romer (op. cit.) insist that the relationship between performance and human

capital is an indirect one; performance is a function of technology, and it is technology that is a function of human capital. One or all three of these explanations may be appropriate to USRATLs. However, the model used here takes the argument one step further by showing that Native American infrastructures are weak and that their superstructures are resistant to human capital formation, i.e.,

$$\left| \frac{\partial(Y_i y_i)}{\partial S_i} \right| < \left| \frac{\partial(Y_i y_i)}{\partial \bar{q}_i} \right| \quad (10)$$

Eq.(10) can be interpreted as meaning that H_i and L_i are close substitutes, which in turn suggests that H_i is either not differentiated from L_i or it is under-employed. Either way there is an institutional disconnect that calls for either the strengthening of infrastructures or weakening the resistance of superstructures. Right now it appears that USRATLs do not believe that human capital is in their economic interests. If correct, such a belief clogs up the Nelson-Phelps channel through which A_j was supposed to flow.

The results also show that the economic conditions of the U.S. and U.S. state economies are important to the performance of USRATLs. Even so, there is no getting away from the fact that unless infrastructural forces and superstructural forces are realigned, the positive effect of human capital on performance will remain constrained. To benefit from human capital accumulation, and through it economic performance, it is imperative that the forces of infrastructure and superstructure are allied, or friction between them minimized.

The results indicate three other areas of further research. First, there is a need for better time-series and/or pooled data in general, and K data in particular. Second, it would be useful to consider why the constant terms are large. One way of doing that may be to account for reservation scale (size) effects, or

to separate A_i from A_j . Third, I have deliberately ignored following the counsel of the econometric purist by leaving statistically insignificant variables in some regressions. My judgment is that the tradeoff between significance and substance was worth the loss of elegance. The technical efficiency of parameters is obviously important, but for now it belongs to a different project.
