False Prophet, or Genuine Savior? Assessing the Effects of Economic Openness on Sustainable Development, 1980–1999

Abstract

While many herald globalization—the increasing interconnectedness of national economies—to be associated with rising standards of living across the globe, others fear its effects on sustainability. Anti-globalization forces and environmentalists view these developments as a threat to the welfare of future generations because of profligate and excessive current consumption. This study is the first to estimate the effects of dependence on trade, foreign direct investment (FDI), and an index of economic freedom on the World Bank’s measure of sustainability (the genuine savings rate), which measures the rate at which investment in the total stock of manufactured, human, and natural capital exceeds its depreciation. Contrary to pessimists’ fears, our indicators of economic openness show positive effects on sustainability, results that are robust to sample size, testing procedure, and several alternative specifications. The results support those who suggest that distorted economies tend to be both inefficient and damaging to future generations. If increasing trade, foreign direct investment, and economic freedom are hallmarks of globalization, then worries about its effects on future well-being are misplaced.

This version: October 2004

While many view growing economic interdependence as good for global prosperity, others fear its effects on sustainability (Mikesell 1992; Neumayer 2003; Pearce and Warford 1993; WCED 1987). The pessimists expect the fierce competition resulting from market globalization and enhanced economic freedom to push countries into unsustainable patterns of resource depletion and economic production, maximizing current profits at the expense of future welfare (MacNeill, Winsemius, and Yakushiji 1991; Meadows, Meadows, and Randers 1993). Optimists, among them most economists, argue instead that market globalization and economic freedom lead to a more efficient allocation of resources by enhancing the role of relative prices and by punishing inefficient policy-making, which should promote both current and future welfare (World Bank 1992; Pearce and Warford 1993; Neumayer 2002a; Bhagwati 2004).

This study will examine the effects of openness to trade and foreign direct investment (FDI) and an index of economic freedom on national rates of genuine savings (adjusted net savings), a broad indicator of (weak) sustainability with wide coverage spanning a period of 20 years (Atkinson and Hamilton 2003; Hamilton 2001; World Bank 1997).¹ It is a measure of the rate at which investment in manufactured, human, and natural capital exceeds its depreciation (World Bank 2002). This measure is based on a widely held precept that sustainable development is the ability to maintain (increase) the aggregate value of manufactured, human, and natural capital, with natural capital being defined as anything in nature providing value to human beings (Atkinson et al. 1999; Goodwin 2003; Hamilton and Clemens 1999; Mikesell 1992). Atkinson and Hamilton (2003: 1804) conclude a recent paper by suggesting that ‘it would be interesting in future work to examine the determinants of the genuine savings rate’. This is the

¹ The term ‘genuine savings’ (GS) was coined by Kirk Hamilton and subsequently appears as ‘net adjusted savings’ in the World Development Indicators.

first study to test the effects of market globalization and economic freedom on genuine savings. We find positive and statistically significant effects that are robust toward a whole battery of sensitivity tests by way of different estimation techniques, inclusion of different control variables, and various sub-samples of the data.

Today, the World Bank and other organizations devoted to development distinguish between ‘good’ and ‘bad’ growth (Thomas et al. 2000). The World Bank’s genuine savings rate is a result of this new thinking. Because the assumption of this approach is that substitutability between various forms of capital is high, this measure is admittedly one that captures ‘weak sustainability’ (Costanza and Jørgensen 2002; Neumayer 2004; Pearce and Atkinson 1993). In contrast, strong sustainability is the view that all natural capital should be kept intact and that substitutability between forms of capital is not possible. Strong sustainability arguments in the globalization debate, however, are less prevalent given the preoccupation of both the right and left with the creation of jobs, economic growth, and concerns over relative economic well-being. In fact, strong environmentalism, largely prevalent in the North, views sustainable development to be a contradiction in terms. One popular measure of strong sustainability is the concept of ‘ecological footprints’ (EF). This concept relates to the amount of environmental resources, defined as the available area of land (habitat), required for sustaining the current levels of consumption as well as for absorbing waste and pollution resulting from consumption (Wackernagel et al. 1999). This concept gives little room for the substitution of environmental resources with manufactured capital, nor can it adequately account for trade as a substitute for scarcity—Singaporeans have more (and better) water resources at their disposal than large resource wealthy states such as Nigeria, the Democratic Republic of Congo, or Angola because human and manufactured capital compensate for natural resource scarcity. In this paper we

mainly focus on how increasing globalization determines a state's chances for achieving weak sustainability. We believe that any conception of sustainability must leave at least some room for substitutability (we do not think that universities should not be built if trees have to be destroyed). Also, weak sustainability is a necessary condition for achieving strong sustainability. In addition, we also briefly address the issue of strong sustainability.

Estimating the effect of globalization and economic freedom on weak sustainability is not just an academic question. Policymakers at many levels seek to harmonize urgent societal requirements, such as growth of income, employment, and general well-being, while ensuring intra- and inter-generational equity. Many recognize that current economic accounting does not fully reflect the trade-offs among various forms of capital (Dasgupta 2001; MEA 2003). For example, economic rents derived from resource extraction and tree cutting do not fully represent income since part of the rents represent depreciation of the natural capital stock. Similarly, economic development that comes at the expense of environmental harm may reduce future well-being. The green accounting program within economics seeks to value investment and depreciation of all forms of capital so that trade-offs among various forms of capital can be better accounted for. The maintenance of all forms of capital that are valuable for production and consumption is regarded as a desirable goal, a notion widely accepted by the pioneers in the profession who seek to measure sustainability so as to translate knowledge into policy (Pearce and Warford 1993). The paper is organized as follows: first, we examine arguments about globalization and economic sustainability, examine the relevance of genuine savings as an important empirical indicator measuring the concept of sustainability, present results, and conclude.

Economic Openness and Sustainability

This study approaches the question of globalization and sustainability from a national perspective by measuring the degree to which states are exposed to, or are connected with, the global economic system. It is standard practice to measure globalization as ‘interconnectedness’ through trade and FDI penetration (Birdsall and Lawrence 1999; Nye and Donahue 2000). According to Mikesell (1992: 141), ‘a comprehensive treatise on sustainable development should integrate the macroeconomics of conventional development with the special concern of natural resource sustainability and environmental protection’ (Mikesell 1992: 141). This study attempts to address the concerns of conventional development economists who see globalization as a source of good, since it promotes growth and development, and environmental economists who argue that globalization may promote profligate patterns of production and consumption that comes at the expense of environmental harm and resource depletion.

Supporters of globalization argue that greater interdependence between rich and poor states and the liberalization of markets from the clutches of profligate governments will enhance wealth, increase efficiency, and destroy the barriers against international environmental cooperation.² Trade liberalization is seen as promoting economic growth (Krueger 1998; Greenaway, Morgan and Wright 1998; Frankel and Romer 1999; Wacziarg and Welch 2003), which in turn is regarded as beneficial to sustainability, at least in the long run (Bhagwati 2004; Frankel 2003). Similarly, FDI is thought to supply poor countries with markets, transfer technology and capital, and above all, provide income growth, employment and poverty

² Some scholars estimate the impact of globalization on government spending to assess whether governments ‘race to the bottom.’ Much evidence seems to suggest that governments adapt to the increasing competition by compensating society with public goods, such as education (Adserà and Boix 2002; Garrett 1998; Rodrik 1996).

reduction (Borenzstein, de Gregorio, and Lee 1998; Cooper 2001; de Mello 1999; de Soysa and Oneal 1999; Klein, Aaron, and Hadjmichael n.d.). The theoretical argument on the beneficial effect of income growth on sustainability is that poverty supposedly pollutes and that demand for environmental quality is a normal, if not luxury good. Poor people degrade the environment through such practices as slash-and-burn agriculture, employ outmoded and inefficient production systems, remain poor by being dependent on natural resource exports, burn biomass that drives the greenhouse effect, and they are highly dependent on burning fossil fuels for energy, particularly coal. Demand for and the economy's capacity to supply strict environmental regulation increases with rising income (Copeland and Taylor 2003). Empirically, economists have tried to demonstrate the link via the so-called 'Environmental Kuznets Curve' (EKC). Accordingly, environmental quality is expected to worsen with increasing income, but only initially, and then improve after a certain threshold, computed by some to be around \$5000 to \$8000 per capita, depending on which pollutant one looks at (Grossman and Krueger 1995).

In addition to the income effect, trade and FDI allow the efficient allocation of resources across the world, where a country specializes in those activities it has an advantage in so that countries with an abundance of one resource can trade with those that are abundant in another, thereby achieving maximum output for a given input—in other words movement towards sustainability because waste is minimized (Brack 1995). Openness to trade is also associated with getting prices right and ending distortions, which enhances sustainability. Governments are likely to subsidize economic activity for political reasons, thereby increasing waste, a policy that is highly costly and becomes increasingly untenable the more exposed a country is to global markets (Birdsall and Wheeler 2001; Yu 1994). Economic openness is therefore often taken as a proxy for good economic policies. Open trading regimes are also more amenable to spreading

newer, better technologies faster than more closed regimes (Perkins and Neumayer 2004). Since environmentally friendly production is likely to be lucrative as people value the environment more, such production technologies will be adopted faster where the market determines the prices. The adoption of such technologies across integrated space may lead to the ‘leveling up’ when laggards are forced by the market to standardize.³ Liberals therefore conclude that autarkic policies and government-dominated markets cause high environmental damage and low output. The experience of state planning exemplified by the former USSR demonstrates that unsustainable management of resources, inefficient economic production, and inadequate channels for civil society to affect policies results in bad outcomes for people and the planet.⁴ Globalization critics therefore ‘fight the wrong enemy’ (Graham 2000).

Finally, while both camps recognize that protecting the global commons requires real international cooperation, with some even calling for a World Environment Organization to rival the World Trade Organization, free traders view the interdependence among countries as a potent driver of environmental cooperation (Haas, Keohane, and Levy 1993). Countries more open to trade are more likely to have signed and ratified important multilateral environmental agreements (Neumayer 2002). In this light, states that trade more with each other potentially have common cause and incentive to cooperate, an age old precept articulated most thoroughly by such

³ The German decision to make catalytic converters mandatory in new cars, for example, was largely because car manufacturers were already tooled to produce cars for the US market, which had required catalytic converters almost a decade previously. This effect is called the trading-up of environmental standards (Vogel 1995).

⁴ The Aral sea catastrophe makes one wonder whether any planner in the USSR asked whether the cotton was worth the sea. Possibly, fish and tourism, among other activities, might have been more economical, not to mention beneficial in other respects too, for the people of the area. Such examples of environmental waste are quite numerous across the globe (Ascher 1999).

philosophers as Immanuel Kant, Montesquieu, and the Manchester school (Russett and Oneal 2000).

Critics counter these arguments by stating that globalization exploits poor countries and constrains the degree to which they are able to achieve sustainability. Some highly popularized, anecdotal and journalistic arguments suggest that globalization leads to ‘global pillage’ (Brecher and Costello 1994). Anti-globalization activists successfully scuttled the Multilateral Agreement on Investment (MAI) on the basis that it would allow corporations to destroy the global commons. Giant corporations are accused of ‘stealing’ the patrimony of the poor and the unborn for conspicuous consumption by the rich (Hardt and Negri 2000; Korten 2001; Martin and Schumann 1997; Zammit 2003):

The pursuit of high and rising consumption in the North and of development in the South have together led to the increasing exploitation of natural resources in unsustainable ways, often by TNC investment in resource-extractive industries in developing countries (Zammit 2003: 137).

In the perspective of its critics, globalization leads to cost cutting, not efficient allocation of resources, and to downward pressure on environmental and social standards:

Policies focusing on liberalization, deregulation and export orientation respond to the logic of short-term profit maximization and international competition that intensifies the need for cost-cutting. The result is the rapacious exploitation and wasteful use of natural resources (Zammit 2003: 137).

Some critics of globalization also assert that increasing trade and specialization may work against efficiency viewed in terms of the dependent nature of most poor countries on the export of primary commodities. Increased trade may snare the poor countries in a ‘specialization trap’ that locks them into servicing a world market growing ever more hungry for resources (Røpke 1994). Others have argued that political structures within countries favor capital at the expense of resource protection, which leads to the subsidization of foreign investors at the expense of

sustainability (López 2003). More generally, critics of globalization argue that trade agreements bind countries to standardized laws and regulations that will reduce the ability for governments and societies to make autonomous decisions by addressing local problems with local solutions. Moreover, critics argue that the systemic interdependence takes away agency from LDC governments. Greater integration of developing countries in market relations diminishes their capacity to act independently because they become locked in dependent relations with the rich. Countries more dependent on trade and investment are expected not to be able to follow sustainable paths of development because it would be against the interests of international capital (Grimes and Kentor 2003; Roberts and Grimes 1997; York, Rosa, and Dietz 2003).

Many pessimists argue that increasing income alone will not automatically take care of environmental problems, since the level of income of many poor countries is so low that increased consumption in rich areas will place too great a burden on an already overloaded planet, long before the poor get rich (Daily and Ehrlich 1996; Daly 1993; Ekins, Folke, and Costanza 1994). In other words, increased economic activity across the globe can magnify the effects of human activity on the ecosystem, leading to collapse (Mabey and McNally 1998). Pessimists also contest the notion that poverty pollutes more than wealth on grounds that the rich consume and waste more. In other words, the luxurious 'greed' of the rich cannot be compared with the survival 'needs' of the poor. These analysts suggest that increased trade will accentuate the profligacy of the already rich. The rich will expand their consumption possibilities at the expense of the poor by displacing the environmental costs on them (Fernando 2003). This proposition relates to what many term the 'pollution haven hypothesis,' whereby polluting industries move from more stringent regulatory environments to lax ones.

The debate between defenders and critics of globalization mirrors older theoretical splits in the social sciences, which pitted dependency/world systems theorists against liberals and modernization theorists concerning the fundamental nature of whether or not closer contact between rich and poor results in exploitative outcomes, such as poverty, the export of pollution, and environmental degradation.⁵ Dependency theorists challenge the liberal view by arguing that international interdependence is neo-colonialism, a system of exploitation, which leads to distorted LDC economies, lowered levels of democracy, and the breakdown of social relations (Amin 1990). They suggest that openness to the world economy leads to the ‘decapitalization’ of poor countries because of the intensification of inappropriate consumption, lowered domestic savings, and capital repatriation by foreign companies (Bornschieer and Chase-Dunn 1985). They also argue that free trade results in uneven development and a divided planet within which cooperation required for environmental protection may not be forthcoming.⁶ Their exhortations are generally to find alternative paths to free-market capitalism (Fernando 2003). World-systems theory similarly views closer contact between rich and poor as a barrier against endogenously determined paths of progress (Bornschieer and Chase-Dunn 1985; Cardoso and Faletto 1979; Galtung 1971; Hoogvelt 2001).

We contend that the longer-term effects of market globalization and economic openness on sustainability can be judged by examining the effects of trade dependence, dependence on FDI, and the level of economic freedom on patterns of savings of physical, human, and natural capital over time (Mikesell 1992). This study asks to what extent globalization promotes, or hinders the

⁵ For a review of long-standing theoretical debates and empirical evidence in political science and sociology concerning the effects of MNCs on development, see de Soysa (2003).

⁶ For an excellent treatment of the differing perspectives, see Gilpin (2000).

achievement of weak sustainability. If globalization represents an extractive, exploitative, top-down project, as the critics claim, then its effect on the accumulation of physical, human, and natural capital stocks over time should provide some indication of the expected harm.

Measuring Weak Sustainability

There are several operational definitions of sustainable development and methods for calculating measures and indexes of sustainability (Neumayer 2004). This study's definition is very close to the spirit of the original, which is 'development that meets the needs of the present without compromising the ability of future generations to meet their own needs' (WCED 1987: 89). In other words, the steady depletion, or degradation of physical, natural, or human capital without offsetting gains may be deemed unsustainable. As some claim quite simply, savings of all forms of capital is the essence of sustainability (Atkinson et al. 1999).

Until quite recently, economists viewed the growth of gross domestic product (GDP) as a measure of development. GDP and the investment required for the growth of output were thought of as involving merely manufactured and, perhaps, human capital. The degradation of natural capital in the process of economic activity was unaccounted in GDP statistics. Green accounting processes began as an important corrective for making GDP reflect the degradation of the natural environment as a consequence of economic production. As a result, the World Bank embarked on estimating the 'Wealth of Nations' to include manufactured, human, and natural capital of countries as a first step towards monitoring the progress of nations in terms of sustainability (World Bank 1997). The changes in the redefined estimates of wealth, therefore, indicate the sustainability/unsustainability of a development trajectory of any given country over time. Importantly, however, these data also show that the most important component of most

nations' capital stocks is human capital (unfortunately, social capital is left out of the calculations because of the complex issues surrounding its measurability).

Our own calculations based on these data reveal that the poorest countries have much natural capital, but a relative lack of human capital.⁷ These data show that the poorest countries have roughly five times more natural capital in total wealth compared with what the richest countries possess.⁸ As countries grow rich their dependence on natural wealth becomes minimal. Indeed, the smallest wealth-gap between rich and poor countries in per capita terms is natural wealth. The share of the poorest countries' per capita natural wealth in the richest countries' total is roughly 65%, even though they only have 2% of the per capita income. Thus, what the poor lack relative to the rich is not natural capital (in per capita terms), but human and manufactured capital.

The importance of genuine savings stems from its ability to indicate whether changes in the total capital stock are beneficial or detrimental to future well-being. As Dasgupta (2001: 87) has written,

Genuine investment is the social worth of net changes in an economy's capital assets. It is a comprehensive notion, including

⁷ These data are constructed for roughly 100 countries for the year 1994 and represent the first disaggregated measure of the actual wealth of nations. The data are values for total natural capital composed of cropland, land, pasture, timber, non-timber assets, protected areas, and all subsoil resources (minerals). Human capital is computed as the value of labor based on education and health, and manufactured capital consists of man-made objects such as buildings, roads, ports etc. The construction of the data is explained in several studies (Hamilton and Clemens 1999; Kunte et al. 1998) and on the World Bank's department of environment website:

<http://lnweb18.worldbank.org/ESSD/envext.nsf/41ByDocName/Environment>

⁸ The poorest countries are the World Bank's (2002) list of "Low Income" countries and the richest are the "High Income" category.

as it does the social worth of net changes in manufactured and human capital, public knowledge, and natural capital. Thus, ensuring that social well-being is sustainable involves taking care that the economy's assets are managed well.

The genuine savings rate, or genuine investment rate as Dasgupta (2001) prefers to call it, is one effort to estimate the sustainability path of nations based on how 'well' they manage their total capital stock. How 'well' then is highly dependent on the environmental costs based on damage to atmosphere (CO₂) and depreciation of the natural resource stock (forest, mineral, and energy stocks). While resource-wealthy countries, such as oil producers, would naturally have higher depletion, policies governing the decisions to spend on education and other investments in capital may more than offset the given depletion. Such countries, however, rarely make these forms of investment, which means that their future well-being is jeopardized by an unsustainable path of resource extraction (Atkinson and Hamilton 2003; Hamilton 2001).

While some argue over the exact method of calculating resource depletion and some problematic assumptions surrounding the concept and its measurement (Neumayer 2000), this study accepts the adequacy of the World Bank's method for current purposes. Naturally, nothing stops anyone from continually testing the conflicting theories against better data as they become available. The multidimensionality of the measure of sustainability that the genuine savings rate presents, however, makes it an attractive choice for addressing the larger issue of how globalization may influence well-being of nations over time. An additional advantage of this measure of sustainability is that it is widely available in time-series format, is consistent with most orthodox views that see economic activity requiring trade-offs, and is a measure policymakers readily understand and would be able to respond to meaningfully (Atkinson and Hamilton 2003).

The basic equation for calculating the genuine savings rate is:

$$\text{GS} = (\text{investment in manufactured capital} - \text{net foreign borrowing} + \text{net official transfers} - \text{depreciation of manufactured capital} + \text{current education expenditures} - \text{net depreciation of natural capital and cost of atmospheric pollution}) / \text{Gross National Income (GNI)}$$

Note that investment in manufactured capital minus foreign borrowing plus net official transfers minus depreciation of manufactured capital is equal to net national savings. While the traditional national accounting treats government spending on education as consumption, the adjusted savings treats it as investment. This is regarded as a first approximation to the full value of human capital investment, which is difficult to measure precisely. Depreciation of natural capital covers non-renewable resource extraction such as fossil fuels and minerals as well as forestry. Cost of atmospheric pollution is approximated by the damage caused by carbon dioxide emissions. Detailed definitions of each item are provided in appendix 1. Investment in manufactured capital “anchors” the genuine savings rate as it forms the starting point from which items are added and subtracted. Across countries, resource depletion and investment in human capital represent the major correction components to net national savings with the cost of atmospheric pollution playing a smaller role. With a mean value of 2.88 per cent of gross national income, resource depletion is not quite as important on average as educational expenditures at 3.94 per cent. Still, it is important given that the mean value of net national savings is 8.87 per cent. Also, its standard deviation is quite high (4.85), and for some resource-intensive countries, the resource depletion component can actually be almost as big as, or in many cases even bigger, than net national savings. Appendix 2 lists each country’s genuine savings rates and its change, both averaged over the entire period of study.

Statistical Methods & Data

This study employs a pooled, time-series, cross-section (TSCS) dataset. The data are for roughly 135 countries, spanning 20 years, and are taken from World Bank (2002). The data for Angola and Sudan only are from World Bank (2003a) since their values seem to be reported with errors in the previous version. The dataset is unbalanced and contains over 2000 data points (an average of about 15 country-years). There are no clear models to guide the determinants of genuine savings. We control for the following factors because of their connection to the main globalization variables and direct effects on the dependent variable. We account for important factors predicting the gross savings rate, so as to control as fully as possible, but parsimoniously, for determinants of manufactured capital savings that may relate to genuine savings directly and to our globalization variables.⁹ Note that fiscal policy variables such as government expenditures, tax revenues etc. cannot be included in the estimations since income minus private and government consumption expenditures is equal to investment and they thus form part of GS.¹⁰ Their inclusion would therefore effectively construct a partial identity between the left-hand side and the right-hand side of the equation. The same argument applies to measures of public debt since net foreign borrowing forms part of GS.

⁹ We have largely relied on the World Bank's research program on savings across the world to pick several variables found to be associated with public and private savings rates (Loayza et al. 1998). The basic model employs per capita income, its growth rate, and urbanization — variables that have data points for at least 135 countries. For robustness, we also test broad money supply (M2/GDP), and the age dependency ratio. Using these variables lowers the sample of countries considerably. The World Bank's research on savings can be accessed at:

<http://www.worldbank.org/research/projects/savings/savinwld.htm>.

¹⁰ Note that some forms of government induced inefficiencies will be captured by our measure of economic freedom, albeit imperfectly.

Our measure of dependence on trade is total trade to GDP [(imports+exports)/GDP]. All data are taken from the WDI (2002) unless noted otherwise. FDI dependence is stock to GDP obtained from the United Nations, which is the most comprehensive data on the activities of MNCs in poor countries (UNCTAD 2003).¹¹ The stock of FDI is accumulated investment over time, which captures the structural power of MNCs over a host economy to a greater degree than do FDI flows alone (Bornschiefer and Chase-Dunn 1985; de Soysa and Oneal 1999; Grimes and Kentor 2003). Trade and FDI are logged to reduce skewness.

The hypothesis of the supporters of globalization is that trade and investment openness lead to “good” economic, market-oriented policies. Often, such openness is used as an indirect proxy for such policies. In addition, we also want to test the impact of an admittedly subjective, but direct measure of good economic policies, namely the Fraser Institute’s index of economic freedom (Gwartney and Lawson 2003). It is made up of roughly 35 components of objective indicators capturing the extent of economic freedom within countries. The index measures freedom of economic activity according to the following criteria in quintiles since 1980 (see www.freetheworld.com for details):

- a. size of government based on spending and the level of state ownership of enterprises
- b. strength of legal system and sanctity of private property rights
- c. access to sound money
- d. freedom to exchange with foreigners
- e. the extent of regulation of economic activity

The missing years for this variable are interpolated. Since the score on economic freedom changes slowly between the five years periods measured, the interpolated values should not be problematic. Strictly speaking, since economic freedom has government size as one of its

¹¹ The foreign investment stock data are available from www.unctad.org.

components, to some extent it also suffers from the problem that its inclusion effectively constructs a partial identity between the left-hand side and right-hand side of the estimation (see above). Fortunately, it is only one out of many components, which should mitigate the problem.

While openness to trade and FDI figure quite prominently in assessing economic freedom, they are but a small part of the overall measure. The bivariate correlations between economic freedom and trade and FDI, nonetheless, are $r = 0.36$ and $r = 0.33$ respectively. Clearly, the indicator of economic freedom captures aspects of open and market-oriented economic policies beyond what trade and FDI alone are able to capture. Using the economic freedom measure as an added factor in the globalization process has additional value since much argumentation about globalization's effects on sustainability reflects fears about growing economic freedom at the expense of government's ability to regulate the market for the sake of intergenerational equity.

The baseline model controls for level of per capita income since richer countries have higher savings rates and supposedly exhibit better environmental standards on several dimensions (Bhagwati 1999; Frankel 2003; Loayza, Schmidt-Hebbel, and Serven 2000; Ogaki, Ostry, and Reinhart 1995; Shafik 1994). Gross national income per capita in purchasing power parity is logged to account for its skewed distribution. We also include a squared term to allow for a diminishing effect of per capita income on sustainability. In addition to income, we follow others (Grimes and Kentor 2003) and account for the structure of production by including the percentage of GDP devoted to agriculture. We control for economic growth, since it is often thought that higher rates of growth require more intensive use of environmental resources. On the other hand, higher growth may enable increases in other forms of capital, such as manufactured and human capital that reduces the direct dependence of people on natural resources (Coxhead and Jayasuriya 2003; Loayza et al. 1998).

Savings rates might be negatively affected if a country undergoes a financial currency crisis. To control for this possibility we include a dummy variable. This is set to one if, following Frankel and Rose (1996), the local currency loses at least 25 per cent of its value and the change in the exchange rate exceeds the previous year's change by at least 10 per cent. The latter accounts for periods of high inflation. The change in the exchange rate is defined as the change in the natural logarithm of the nominal bilateral dollar exchange rate.

The models include the degree to which countries are dependent on natural resource exports because resource depletion will be higher among these countries. As the early studies of the genuine savings data indicate, energy rich states in particular tend to have low genuine savings given the high extraction levels of a single resource, coupled with lower than normal investment in human capital, dimensions of the familiar 'resource curse' hypothesis highlighted in the literature (Atkinson and Hamilton 2003; Hamilton 2001). The resource curse is blamed on economic, political, and social factors, all of which are possible avenues through which sustainability may be hampered (Auty 2001; Gylfason 2000; Ross 1999; Sachs and Warner 2001). We control for resource dependence in two ways. First, we test a discrete variable that takes the value of one if exports of petroleum are greater than 50% of GDP. This measure is obtained from an independent source (Easterly and Sewadeh 2001). Secondly, we employ continuous measures for fuels and ores and mineral exports in total merchandise exports. These variables are obtained from World Bank (2002).

Democracy, it is often argued, is good for environmental protection because it empowers people and provides channels through which governments can be influenced by civil society (Dryzek 1997; Frankel 2003; Midlarsky 2001). Democracy also enhances international environmental cooperation (Neumayer 2002b). The rise of green movements, non-governmental

organizations, and other activist movements within democracies is seen as proof of this. Democracy also relates to trade openness, with many arguing that democracy increases openness (Milner 1999). Moreover, democracy also affects the gross savings rate as politics drive tax policies and affect the issue of corruption and rent-seeking behavior. We use the standard polity IV (version 2) data (Gurr and Jagers 1995). We subtract autocratic values from the democratic values and add 11 to create a scale from 1 to 21. We construct a dummy variable for regime type by assigning the value 1 if democracy ranges from 16–21, and 0 if the values are between 1 and 15 (autocracy). This variable correlates perfectly with others who have used the Polity data in a similar manner (Fearon and Laitin 2003).

In addition, we include two further measures of governance as control variables. One is the political constraints (POLCON) index developed by Henisz (2000). Henisz has designed his index as an indicator of the ability of political institutions to make credible commitments to an existing policy regime, which he argues is the most relevant political variable of interest to investors. Building on a simple spatial model of political interaction, the index makes use of the structure of government in a given country and the political views represented by the different levels of government (i.e. the executive, the legislature). It measures the extent to which political actors are constrained in their choice of future policies by the existence of other political actors who will have to consent. Scores range from 0, which indicates that the executive has total political discretion and could change existing policy regimes at any point of time, to 1, which indicates that a change of existing policy regimes is totally infeasible. Of course, in practice agreement is always feasible, so the maximum score is less than 1. Not surprisingly, POLCON is highly correlated with democracy. However, the results reported below hardly change if either of the two variables is dropped from the model to address potential problems with multicollinearity.

The other governance measure captures the stability of the political system by counting the percent of veto players dropping out from government in any given year. This variable is taken from the World Bank's (2003b) Database of Political Institutions.

Trade dependence, the savings rate, and environmental stress are affected by demographic factors (Alesina and Spolaore 1997; MEA 2003).¹² Thus, population size (total population), population density (people per square kilometer), and the share of urban population in total population are included in the models. Urbanization has important implications for levels of pollution and investment in manufactured capital because it is argued that consumption rises with rising urbanization (Shafik 1994). These variables are all logged to minimize the effect of extreme values.

Finally, we enter control variables for experience with armed conflict, which presumably influences savings rates and the degree to which extractive activity, corruption, and accumulation of manufactured capital proceeds. We compute a count of peace years since 1946 employing the Uppsala-PRIO data on civil wars (Gleditsch et al. 2002) and utilizing the BTSCS program in Stata (Beck, Katz, and Tucker 1998).¹³ A civil war is defined as an internal war (with and without foreign intervention) with 1000 battle deaths or more. The incidence of civil war is also

¹² Neo-Malthusian views and anti-globalization views generally coincide on issues of sustainable development. There is lively debate in the literature between the neo-Malthusians and the cornucopians, or those who think substitution of natural resources with human ingenuity is possible. For the classic debate, see (Myers and Simon 1994). Most texts on environmental security and economic sustainability sample this debate (Conca and Dabelko 1998).

¹³ The civil war data can be downloaded from www.prio.no and the BTSCS program for generating the peace years and splines from www.vanderbilt.edu/~rtucker/programs/btscs/.

added to the models to account for ongoing civil war, so as to capture any immediate effects above those of accumulated years of peace.

Appendix 3 provides summary statistics of the variables together with a bivariate correlation matrix. A few correlations are above 0.4. The urbanization rate and the agricultural share are the variables with the greatest number of high correlations. They were also identified as potential problem variables by variance inflation factor analysis. However, dropping these two variables or any of the other control variables with high correlations from the model hardly affects our results.

The analysis of TSCS data generally poses several problems in the estimating process. TSCS data have complicated temporal and spatial structures that simple ordinary least squares (OLS) cannot adequately account for. TSCS models often allow for temporally and serially correlated errors as well as for heteroskedasticity. The well-known Parks method based on generalized least squares (GLS), which is close to the OLS method, is discredited for underestimating the true variability of the parameter estimates, which some report to be as high as 200% (Beck and Katz 1995). Beck and Katz (1995) propose ‘panel corrected standard errors’ (PCSE) together with OLS as an alternative procedure. We follow this procedure, assuming an autoregressive error process of order one (AR1). Note that for this estimator, we replace the year-specific dummies with a linear time trend because the estimated variance-covariance matrix is not positive definite if year dummies are used.¹⁴ For evaluating the robustness of the findings, we also estimate random effects GLS and population averaged models, or the generalized estimation equation (GEE) method, which is yet another testing procedure when the underlying correlation structures in the data are unknown (Zorn 2001). In these estimations, an AR1 error

¹⁴ Results are robust toward replacing the linear time trend with five-year period dummies.

process is also assumed. All estimations pass a Wald- or F-test at conventional significance levels so that in order to save space no test statistics are reported. All the independent variables are lagged one year to mitigate simultaneity bias, although for our main variables of interest at least it will be hard to maintain that increased genuine savings increases trade and FDI dependence, or economic freedom, not the other way around as the literature discussed above indicates.

Results

Over the period of our study, countries below the median of trade openness have an average genuine savings (GS) rate of 4.11% with a standard deviation (SD) of 8.56 compared to the average for countries above the median of 7.79% with a standard deviation of 15.05. For our FDI measure, the respective figures are 6.09 (SD of 8.97) for countries below the median and 5.82 (SD of 15.04) for countries above the median. Countries below the median of the index of economic freedom have an average GS rate of 3.16 (SD of 9.89) compared to 11.19 (SD of 11.08) above the median. Figure I plots the period mean value of the logged trade share against the genuine savings rate, distinguishing between developed OECD-countries, developing countries with below median and developing countries with above median natural resource intensity. Figures II and III do the same for the logged FDI stock to GDP and the measure of economic freedom, respectively.

< Insert Figures I to III around here >

The much larger standard deviations of the more trade and FDI open countries suggest significant differences among this group of countries, which is likely to be rooted in variation in other explanatory variables and stresses the importance of controlling for these differences in our estimations. Indeed, of the ten countries with the lowest GS rate over the period (Azerbaijan,

Democratic Republic of Congo, Kazakhstan, Liberia, Libya, Nigeria, Oman, Saudi Arabia, Yemen, Zambia) eight countries have trade openness and all countries have FDI openness above the median. While at the same time, of the ten countries with the highest GS rate (Belize, Botswana, Japan, Luxembourg, Malta, Namibia, Seychelles, Singapore, South Korea, Thailand) there are also nine and seven countries with trade and FDI openness, respectively, above the median. Clearly, one obvious characteristic of the countries with very low GS rates is that they are mostly natural resource-intensive economies (this can also be clearly discerned from figures III to V). Our multivariate estimations reported below indeed show that resource-intensity is an important determinant of GS. We also take this as further reason to test our hypothesis in a sub-sample of resource-intensive economies. A characteristic of the countries with high GS rates is that some of them clearly have high per capita incomes. This factor points toward the need to control for per capita income to ensure that our measures of trade and FDI openness (as well as economic freedom) do not spuriously pick up an effect that truly belongs to the level of economic development. It also prompts us to test our hypotheses in sub-samples of developing and low-income countries.

Turning to our multivariate analysis, table 1 presents the results of trade and FDI's effects on the genuine savings rate utilizing three estimation procedures, the random effects GLS, the GEE, and the PCSE methods. As seen there, in columns 1 and 2, both trade and FDI dependence are positively and statistically significantly associated with the genuine savings rate using the random effects GLS method if entered separately into the estimations. The statistical significance of the trade variable is confirmed in column 4 when GEE is used, but the FDI variable becomes

marginally insignificant in column 5.¹⁵ Both variables are significant again in columns 7 and 8 when the PCSE method is employed. When both FDI and trade are entered in the regression together (columns 3, 6 and 9), then both variables remain positive with trade retaining its statistical significance, but FDI becoming statistically insignificant. With a bivariate correlation of $r = 0.44$, it seems that trade openness masks the effects of FDI on the GS rate, if entered together.

When entered into the regressions separately, then, in comparison, trade openness is the substantively more important variable of the two. A one SD increase in trade openness raises the GS rate by up to 1.5 percentage points, compared to up to 0.86 percentage points for a one SD increase in the FDI measure. These values do not seem very high, but keep in mind that the average GS rate across the period is only 6.95 per cent. Also, the standard deviations are relatively small for our measures of economic openness as many countries are clustered around the mean value. If we look at the effect of moving from the least open to the most open regimes instead, then this raises the GS rates by up to 11.15 and 7.9 points in the case of trade and FDI openness, respectively. Another way to demonstrate the effect of economic openness is to look at predicted values from the estimations. Based on the regression models 7 and 8, the average predicted genuine savings rates for the countries with trade and FDI openness below the median are 5.10 and 5.61 per cent, respectively, whereas the relevant values for countries with openness above the median are 8.19 and 7.43 per cent, respectively. These predicted rates are close to the actual averages from the bivariate analysis reported above, which suggests that the observed

¹⁵ Note that the GEE estimator drops Lebanon from the regression as this country has only one observation in the time period, which is not enough to estimate the necessary correlation statistic for this estimator.

differences between relatively closed and relatively open economies uphold after controlling for several important determinants of genuine savings.

Notice that all the three methods used for the analysis of the data produce somewhat similar results on our control variables. Per capita income is strongly positively associated with genuine savings across the testing procedures. However, the effect is non-linear suggesting that per capita income raises genuine savings with diminishing returns. The economic growth rate is not statistically significant. Given that higher income levels are good for genuine savings, growth's long-term, accumulated effect should be positive, however. A higher percentage of an economy devoted to agriculture is negative for accumulating genuine savings in columns 7 and 8. This result provides some limited support to those who argue that the modernization of economies promotes sustainability. Events of currency crises do not lower the GS rate. Dependence on oil extraction has a strong negative effect on the genuine savings rate as others have also reported (Hamilton 2001). This result is statistically highly significant and substantively very large. Being an oil export-dependent country lowers the genuine savings rate by an average of roughly 20 percentage points.

Democracy's effect on genuine savings is positive and statistically significant only in the last two columns when the PCSE method is used. Our results suggest that democracy's actual performance does not necessarily match the degree of emphasis on this variable in the academic and popular discussions on sustainability. However, its positive effect, even if only statistically significant in PCSE estimation, is encouraging and warrants closer analysis. Moreover, given our crude dichotomization of the Polity measure, future research should focus on disaggregating types of democracies, as differing democratic institutions produce varying policy outcomes (de

Soysa 2003; Lijphart 1994; Powell 2000). At the same time, we find that neither constraints on policy makers nor governmental stability affect the GS rate.

More densely populated societies are associated with higher genuine savings rates, contrary to the pervasive neo-Malthusian discussions on sustainable development. In other words, population pressure within a territorial unit does not inhibit genuine savings, but it promotes it, net of the other control variables in the model, such as income. Population size, on the other hand, is negative, but the results are far from statistical significance. Higher percentages of urban population, net of the influence of the other control variables, seem to be detrimental to the GS rate.

Civil war experience lowers the genuine savings rate, but a longer period of peace exerts a positive and statistically significant effect only in columns 7 to 9. These results are net of income. Given war's detrimental effects on income, the overall effect on gains to genuine savings from peace is bigger still. This interesting subject too warrants further reflection and more analysis given the recent theoretical arguments about natural resource dependence and civil war (Collier et al. 2003).

Are our results generated by the presence of developed countries in the sample? To provide a fair test of the effect of globalization on sustainability, we need to check whether our results uphold for the countries critics of globalization are most concerned about. In table 2, we repeat estimations for sub-samples of countries. To save space, we concentrate on results from PCSE estimations. In columns 1 and 2, we restrict the sample to developing countries, dropping Japan, Australia, New Zealand, Northern American and Western European countries. In columns 3 and 4, we further restrict the sample to countries classified as falling into the low-income category by the World Bank. In columns 5 and 6, we check whether results uphold for those developing

countries, which trade more than proportionally with OECD-countries by restricting the sample to countries whose trade with OECD-countries divided by GDP is above the median value. Next, we want to explore whether trade openness and FDI raise genuine savings also in developing countries that are particularly reliant on natural resource extraction. For this purpose, in columns 6 and 7 we restrict the sample to countries whose rents from natural resource extraction relative to their gross national income (GNI) is in the upper three quartiles. Lastly, columns 8 and 9 further restrict the sample to developing countries with resource rents to GNI above the median. The most interesting feature in these estimations is that despite variances in sample size, FDI remains positive and significant in all estimations as does trade, which is only insignificant in column 9. Globalization remains a promoter of sustainability even in groups of countries thought to be the most vulnerable, perhaps with the exception of countries very heavily dependent on natural resource extraction.¹⁶

We have seen already that natural resource intensity has a substantively important impact on the genuine savings rate. So far, we have used a rather crude measure of resource intensity, which had the advantage, however, of being available for a maximum number of countries. In table 3, the dichotomous measure of oil export dependence is substituted by two continuous measures of fuel exports and metals and ores exports as a percentage of merchandise exports. The substitution results in the loss of 10 countries from the sample, but the new resource export measures are more comprehensive, containing more information than the simple dummy variable. While the fuel export dependence variables are correlated at $r = 0.80$ with each other, the fuel measures are only weakly correlated with exports of metals and ores. As seen in columns

¹⁶ The domestic political economy of education spending within resource-wealthy countries possibly influences this result; see Gylfason (2000).

1 and 2, the effects of trade and FDI on the genuine savings rate remain positive and statistically highly significant. The results of the natural resource variables are both consistent with the findings of others, and the control variables remain pretty much the same except that now, the results on democracy are statistically far from significant. Contrarily, the effect of accumulated years of peace is now consistently statistically significant with the expected positive sign.

In table 4, we report the results of running the models with the measure of economic freedom. We first include only economic freedom, then add trade and FDI openness in separate estimations, finishing with a model that includes all three variables. Economic freedom is positively associated with the genuine savings rate throughout. A one SD increase in the index of economic freedom increases the genuine savings rate by up to 3.25 percentage points, a move from the minimum observed value to the maximum by up to 20.8 points. The predicted average GS rate for the countries below the median of economic freedom is 2.83 per cent, whereas it is 11.74 per cent for the ones above. Results for the rest of the control variables are rather similar to those reported in table 2 above, despite the fact that the number of countries decreases by 26. This suggests again that the results are quite robust to differences in sample size. Trade openness is positive and significant, whereas FDI openness is positive, but insignificant, whether added in isolation or in combination with economic freedom. Restricting the sample to be the same, but including just FDI openness, leads to a positive and highly significant coefficient of this variable (column 5). This suggests that the insignificance of the FDI measure is not due to the reduction in sample size. Instead, as before, the positive effect of FDI openness is masked by the inclusion of other aspects of economic openness with which the FDI variable is correlated.

Are our results driven by country-specific fixed effects such as cultural differences, which we have not explicitly controlled for so far? Table 5 reports results from a fixed-effects GLS

estimator with an assumed AR1 error process. The results on trade, FDI, and economic freedom are not affected. Note that in these fixed effects estimations we found no evidence for a non-linear effect of income on the genuine savings rate, which is why only the linear income term is entered into the regressions. The reason why some of the control variables cease to be statistically significant in these estimations is because they vary little over time (e.g., population density and the urbanization rate) and are thus estimated very inefficiently by the fixed effects estimator, which draws upon the over-time data variation in each country only.

As mentioned, economic openness is often used as a proxy for “good” economic policies. In order to further check whether it was the degree of corruption rather than trade, FDI, or economic freedom that mattered, we tested the models using the International Country Risk Guide’s (ICRG) data on ‘corruption’, which is another widely accepted measure of good governance (Ades and Di Tella 1999; Kaufmann, Kraay, and Zoido-Lobaton 1999; Treisman 2000).¹⁷ The results of the globalization variables were unchanged when corruption was included. This variable turned out to be positive but statistically not different from zero. Including M2/GDP (broad money supply) and the age dependency ratio had little effect on the positive and significant effects of the globalization variables. We did not include portfolio investments in the main estimations since we do not expect these rather volatile investment flows to have any significant effect on the GS rate and also because its inclusion would limit sample size. Running portfolio investment alongside trade and FDI, however, yielded an insignificant effect on this variable, while the results on the other two globalization variables were upheld.

¹⁷ The ICRG data on corruption gauge the degree to which the rule of law prevails. We average the quarterly scores for each year between 1984 and 1999. The data are available for 110 countries in our sample and was obtained from the Political Risk Services (PRS) group, which supplies the data commercially for a fee (www.prs.com).

In summary, the results taken together seem remarkably robust to sample size, specification, and testing procedure. The globalization variables remained unchanged despite several alternative specifications. If the spread of globalization and economic liberalism increase interconnectivity among states, then these trends increase the chances that states would be less profligate. Our results taken together support those who argue that globalization potentially improves conditions for sustainability. If increasing globalization is good for current economic development, our analyses do not suggest that it is to the detriment of future generations. What seems to be harmful for sustainability is autarchy.

So far we have addressed a form of sustainability, which presumes a high degree of substitutability among various forms of capital in the spirit of weak sustainability. The concept of ecological footprints (EF) is a measure in the spirit of strong sustainability, which rejects substitutability. The objective of EF is to translate all the ecological impact of human economic activity into the 'area required to produce the resources consumed and to assimilate the wastes generated ... under the predominant management and production practices in any given year' (Wackernagel et al. 2002, p. 9266). Since the focus is on consumption, the required land area is attributed to the consumer rather than the producer because the consumer is deemed responsible for the environmental impact. For example, resources extracted in a developing country, but exported to a developed country, count towards the ecological footprint of the developed country. The following impacts are included (Wackernagel et al. 2002): (1) crop growing for food, animal feed, fibre, oil and rubber; (2) animal grazing for meat, hides, wool and milk; (3) harvesting of timber for wood, fibre and fuel; (4) fishing in oceans and freshwater; (5) infrastructure for housing, transportation, industrial production and hydro-electric power; and, finally, (6) burning of fossil fuel. Due to data problems, fresh water withdrawal is not included.

Of all the human impacts, accounting for fossil fuel use is the most important one, responsible for slightly less than half of the global EF in 1999. This so-called energy footprint is the one that has grown fastest over the last decades and in which the disparity between the developed and developing countries is largest.

There are many problems with using EF as a measure of ecological sustainability and with estimating how it is affected by globalization. Conceptually, one can argue that EF adds up “apples and oranges” in adding such diverse items as actual land use for agricultural products and purely hypothetical land use for the absorption of carbon dioxide emissions. The energy component is also the most controversial part of EF. It is calculated as the forest land area required to hypothetically sequester enough carbon from the atmosphere to avoid any increase in the atmospheric concentration of carbon from fossil fuel use. There are many more possibilities to sequester carbon from the atmosphere or to prevent carbon emissions than land-intensive forestry, however. Fossil fuel could be replaced with renewable energy, particularly wind and solar energy (Neumayer 2003). IMV (2002) has calculated that the energy footprint becomes negligible with little impact on the overall EF if, hypothetically, 50% of world energy demand were satisfied with renewable energy, which IMV (2002) claims to be technically possible, and for the remaining energy demand, low carbon fuels such as natural gas are used. From the practical side, a major drawback of the variable is that EF have only been calculated for a global sample for three years, namely 1996, 1999 and 2000 (WWF 2002, 2004).

These problems notwithstanding, table 6 reports results for EF as the dependent variable (appendix 2 lists each country’s ecological footprint and its change, both averaged over the entire period of study). We use the GLS estimator with random effects as the PCSE estimator is not the most suitable for very short time periods. The stability of the political system variable from the

World Bank database was not lagged in these estimations, which would not have allowed us to use the EF value for the year 2000. Neither trade, FDI, nor economic freedom are statistically significant. This remains true also in case the dependent variable is interpolated to gain more observations (not shown). Apart from income, population size, and population density no other variables are significant. Indeed, a model with only per capita income and its squared term explains 80 per cent of the variation in the data! This leaves very little explanatory power for any of the other variables. Higher per capita income first lowers the EF at very low levels of income up to an estimated threshold of around US\$1000, after which higher income is associated with higher EF. It is apparent that the way the EF is constructed, high-income countries have very high EF and poor countries have low EF and there is little else that matters. Any policy recommendation from such a result would inescapably mean “increase poverty,” an untenable position no matter which part of this divided planet one lives in. Interestingly, we find no support for Neo-Malthusian population concerns since countries with bigger populations and higher population density have lower rather than higher ecological footprints.

Conclusion

As one eminent scholar has put it, “reason and analysis require that we abandon the conviction that globalization lacks a human face, an assertion that is tantamount to a false alarm, and embrace the view that it *has* one” (Bhagwati 2004: 265; italics in original). Our estimations support this view. We examined the effects of trade, FDI, and economic freedom on the World Bank’s genuine savings rate, one composite measure of (weak) sustainability. The logic of the measure is that sustainable development requires keeping net savings of all forms of capital that we value at least above zero, thus capturing the trade-offs inherent in the accumulation of some forms of capital at the expense of others. Since even building a school requires the trade-off of

land, trees, other resources etc, analyses of sustainable development have often failed to capture such dimensions in their operationalization. Thus, the question becomes under what conditions countries transform natural resources, including clean air, into income sustainably. Answering this question, our study gauged the effects of trade and FDI dependence and degree of economic freedom on the genuine savings rate over a period of twenty years. Our results are easily summarized.

Trade, FDI dependence and economic freedom increase genuine savings. There does not seem to be reason to fear what some dependency and world system theorists have argued in terms of a capitalist world system damaging the well-being of future generations. This study finds no such effect of globalization. Countries that are more closely integrated into world markets and that allow a greater degree of economic freedom protect their future well-being better than isolated countries that tightly restrict the freedom of economic activity. Allegations that globalization induces countries to maximize short-term benefits at the expense of mortgaging the future are therefore without foundation.

A few country cases can illustrate our main results. Comparing the situation in the first half of the 1980s to the one of the second half of the 1990s, many countries opened their economies and increased their genuine savings rate substantially. For example, Chile and Ghana increased their share of trade to GDP by 14 and 64 percentage points, their FDI stock relative to GDP by 30 and 8 percentage points, and their Index of Economic Freedom by 2.4 and 2.8 points, respectively, while at the same time increasing their genuine savings rate by 22 and 9 percentage points, respectively. Of course, not all countries opened up toward trade and FDI and allowed more economic freedom all at the same rate. China is a good example for this. It increased its trade share by 25 percentage points, its FDI stock relative to GDP by 21 percentage points, but

allowed an increase in economic freedom of merely 0.8 points that is less impressive. In the same time span, the country managed to increase its genuine savings rate by 24 percentage points. Inevitably, there are also some failures, representing exceptions to the general trend. For example, both Nicaragua and the Democratic Republic of Congo were much more open in the late 1990s than in the early 1980s. They increased their trade share by 55 and 20 percentage points, their FDI share by 26 and 4 percentage points and their index of economic freedom by 2 and 0.6 points, respectively. And yet, their genuine savings rate dropped by 5 and 7 percentage points, respectively. In future research, we would like to explore the reasons why some liberalizing countries fail to achieve increases in genuine savings.

Admittedly, our results only hold for weak sustainability. However, such sustainability is a prerequisite for achieving stronger forms of sustainability. Also, whilst we have not been able to demonstrate a positive effect of globalization on strong sustainability, of which ecological footprints represent a crude and contested measure, we have also not found any negative effect. Clearly, more research needs to be done on the determinants of the genuine savings rate beyond globalization concerns, so that econometric models might be refined over time. When stronger findings from other variables can be incorporated, we will be able to test further the potential spuriousness of the association between trade, FDI, economic freedom and sustainability reported here.

This caveat notwithstanding, our results taken together suggest that economic globalization leads to better management of the wealth of nations, a good prospect for the present generation and for those to whom we bequeath the planet. On the other hand, resource-wealthy countries seem to waste resources given that they fail to translate extraction of nature's wealth into sustainability via adequate investment in manufactured and human capital, presumably because

of the well-documented feature of both economic and political ‘Dutch disease’ that often result in distorted markets, corruption, mal-governance, and social breakdown.

Many developing countries have embarked on a policy reform toward economic openness in the last two decades or so (Simmons and Elkins 2004). Whether this change is prompted by the spectacular failure of inward-looking and import-substituting economic policies from previous decades (Rodrik 1994), is a consequence of the process of democratization (Milner and Kubota 2005) or has other reasons altogether need not concern us here. What is important is that, built on our estimations, the gradual adoption of open economic policies even in resource-wealthy regions, such as Africa, is good news for weak sustainability.

Appendix 1: Definitions of components of the Adjusted Net Savings (Genuine Savings)

- Gross national savings are equal to gross domestic investment minus net foreign borrowing plus net official transfers
- Net national savings are equal to gross national savings less the value of consumption of manufactured capital
- Adjusted net savings, or genuine savings, are equal to net national savings plus current education expenditures and minus energy depletion, mineral depletion, net forest depletion, and carbon dioxide damage
- Carbon dioxide damage is estimated as \$20 per ton of carbon (the unit damage in 1995 U.S. dollars) times the number of tons of carbon emitted
- Current education expenditure refers to the current operating expenditures in education, including wages and salaries and excluding capital investments in buildings and equipment
- Energy depletion is equal to the product of unit resource rents and the physical quantities of energy extracted. It covers crude oil, natural gas, and coal
- Mineral depletion is equal to the product of unit resource rents and the physical quantities of minerals extracted. It refers to bauxite, copper, iron, lead, nickel, phosphate, tin, zinc, gold, and silver
- Net forest depletion is calculated as the product of unit resource rents and the excess of roundwood harvest over natural growth.

Appendix 2: Genuine savings rates, ecological footprints and their changes (mean period values).
